14th August 2002

Abstract

This document is intended to be a compilation of tips and tricks mainly related to efficient ways of performing low-level array manipulation in MATLAB. Here, “manipulation” means replicating and rotating arrays or parts of arrays, inserting, extracting, permuting and shifting elements, generating combinations and permutations of elements, run-length encoding and decoding, multiplying and dividing arrays and calculating distance matrices and so forth. A few other issues regarding how to write fast MATLAB code are also covered.

I’d like to thank the following people (in alphabetical order) for their suggestions, spotting typos and other contributions they have made.

Ken Doniger and Dr. Denis Gilbert

1 Introduction

1.1 The motivation for writing this document

Since the early 1990's I have been following the discussions in the main MATLAB newsgroup on Usenet, comp.soft-sys.matlab. I realized that many of the postings in the group were about how to manipulate arrays efficiently, which was something I had a great interest in. Since many of the the same questions appeared again and again, I decided to start collecting what I thought were the most interesting problems and solutions and see if I could compile them into one document. That was the beginning of the document you are now reading.

Instead of just providing a bunch of questions and answers, I have attempted to give general answers, where possible. That way, a solution for a particular problem doesn't just answer that one problem, but rather, that problem and all similar problems.

For a list of frequently asked questions, with answers, see Peter Boettcher's excellent MATLAB FAQ which is posted to the news group comp.soft-sys.matlab regularly and is also available on the web at <http://www.mit.edu/~pwb/cssm/>.

1.2 Who this document is for

This document is mainly intended for the reader who knows the basics of MATLAB and would like to dig further into the material. This document is more of a reference than a tutorial. The language is rather technical although many of the terms used are explained. The index at the back should be an aid in finding the explanation for a term unfamiliar to the reader.

1.3 Credit where credit is due

To the extent possible, I have given credit to what I believe is the author of a particular solution. In many cases there is no single author, since several people have been tweaking and trimming each other's solutions. If I have given credit to the wrong person, please let me know.

In particular, I do not claim to be the sole author of a solution even though there is no other name mentioned.

1.4 Errors and feedback

If you find errors, or have suggestions for improvements, or if there is anything you think should be here but is not, please mail me and I will see what I can do. My address is on the front page of this document.

1.5 Vectorization

The term "vectorization" is frequently associated with MATLAB. It is used and abused to the extent that I think it deserves a section of its own in this introduction. I want to clarify what I put into the term "vectorization".

Strictly speaking, vectorization means to rewrite code so that one takes advantage of the vectorization capabilities of the language being used. In particular, this means that one does scalar operations on multiple elements in one go, instead of using a for-loop iterating over each element in an array. For instance, the five lines

```
x = [ 1 2 3 4 5 ];  
y = zeros(size(x));  
for i = 1:5  
    y(i) = x(i)^2;  
end
```

may be written in the vectorized fashion

```
x = [ 1 2 3 4 5 ];  
y = x.^2;
```

which is faster, more compact, and easier to read. An important aspect of vectorization is that the operation being vectorized should be possible to do in parallel. The order in which the operation is performed on each scalar should be irrelevant. This is the case with the example above. The order in

which the elements are squared does not matter. With this rather strict definition of “vectorization”, vectorized code is always faster than non-vectorized code.

Some people use the term “vectorization” in the loose sense “removing a for-loop”, regardless of what is inside the loop, but I will stick to the former, more strict definition.

2 Operators, functions and special characters

Clearly, it is important to know the language one intends to use. The language is described in the manuals so I won’t repeat here what they say, but I strongly encourage the reader to type

```
help ops
```

at the command prompt and take a look at the list of operators, functions and special characters, and look at the associated help pages.

When manipulating arrays in MATLAB there are some operators and functions that are particularly useful.

2.1 Operators

- `:` The colon operator.
Type `help colon` for more information.
- `.'` Non-conjugate transpose.
Type `help transpose` for more information.
- `'` Complex conjugate transpose.
Type `help ctranspose` for more information.

2.2 Built-in functions

<code>all</code>	True if all elements of a vector are nonzero.
<code>any</code>	True if any element of a vector is nonzero.
<code>cumsum</code>	Cumulative sum of elements.
<code>diag</code>	Diagonal matrices and diagonals of a matrix.
<code>diff</code>	Difference and approximate derivative.
<code>end</code>	Last index in an indexing expression.
<code>eye</code>	Identity matrix.
<code>find</code>	Find indices of nonzero elements.
<code>isempty</code>	True for empty matrix.
<code>isequal</code>	True if arrays are numerically equal.
<code>isfinite</code>	True for finite elements.
<code>isinf</code>	True for infinite elements.
<code>islogical</code>	True for logical array.
<code>isnan</code>	True for Not-a-Number.
<code>isnumeric</code>	True for numeric arrays.
<code>length</code>	Length of vector.
<code>logical</code>	Convert numeric values to logical.
<code>ndims</code>	Number of dimensions.
<code>numel</code>	Number of elements in a matrix.
<code>ones</code>	Ones array.
<code>permute</code>	Permute array dimensions.
<code>prod</code>	Product of elements.
<code>reshape</code>	Change size.
<code>size</code>	Size of matrix.
<code>sort</code>	Sort in ascending order.
<code>sum</code>	Sum of elements.
<code>tril</code>	Extract lower triangular part.
<code>triu</code>	Extract upper triangular part.
<code>zeros</code>	Zeros array.

2.3 M-file functions

<code>flipdim</code>	Flip matrix along specified dimension.
<code>fliplr</code>	Flip matrix in left/right direction.
<code>flipud</code>	Flip matrix in up/down direction.
<code>ind2sub</code>	Multiple subscripts from linear index.
<code>ipermute</code>	Inverse permute array dimensions.
<code>kron</code>	Kronecker tensor product.
<code>linspace</code>	Linearly spaced vector.
<code>ndgrid</code>	Generation of arrays for N-D functions and interpolation.
<code> repmat</code>	Replicate and tile an array.
<code>rot90</code>	Rotate matrix 90 degrees.
<code>shiftdim</code>	Shift dimensions.
<code>squeeze</code>	Remove singleton dimensions.
<code>sub2ind</code>	Linear index from multiple subscripts.

3 Basic array properties

3.1 Size

The size of an array is a row vector with the length along all dimensions. The size of the array `x` can be found with

```
sx = size(x);           % size of x (along all dimensions)
```

The length of the size vector `sx` is the number of dimensions in `x`. That is, `length(size(x))` is identical to `ndims(x)` (see section 3.2.1). No builtin array class in MATLAB has less than two dimensions.

To change the size of an array without changing the number of elements, use `reshape`.

3.1.1 Size along a specific dimension

To get the length along a specific dimension `dim`, of the array `x`, use

```
size(x, dim)           % size of x (along a specific dimension)
```

This will return one for all singleton dimensions (see section 3.2.2), and, in particular, it will return one for all `dim` greater than `ndims(x)`.

3.1.2 Size along multiple dimension

Sometimes one needs to get the size along multiple dimensions. It would be nice if we could use `size(x, dims)`, where `dims` is a vector of dimension numbers, but alas, `size` only allows the dimension argument to be a scalar. We may of course use a for-loop solution:

```
siz = zeros(size(dims));           % initialize size vector to return
for i = 1 : numel(dims)           % loop over the elements in dims
    siz(i) = size(x, dims(i));    % get the size along dimension
end                               % end loop
```

The above works, but a better solution is:

```
siz = ones(size(dims));           % initialize size vector to return
sx = size(x);                   % get size along all dimensions
k = dims <= ndims(x);           % dimensions known not to be trailing singleton
siz(k) = sx(dims(k));           % insert size along dimensions of interest
```

Code like the following is sometimes seen, unfortunately. It might be more intuitive than the above, but it is more fragile since it might use a lot more memory than necessary when `dims` contains a large value.

```
sx = size(x);                   % get size along all dimensions
n = max(dims(:)) - ndims(x);    % number of dimensions to append
sx = [ sx ones(1, n) ];        % pad size vector
siz = sx(dims);                 % extract dimensions of interest
```

An unlikely scenario, but imagine what happens if `x` and `dims` both are scalars and that `dims` is a million. The above code would require more than 8 MB of memory. The suggested solution further above requires a negligible amount of memory. There is no reason to write fragile code when it can easily be avoided.

3.2 Dimensions

3.2.1 Number of dimensions

The number of dimensions of an array is the number of the highest non-singleton dimension (see section 3.2.2) which is no less than two. Builtin arrays in MATLAB always have at least two dimensions. The number of dimensions of an array `x` is

```
dx = ndims(x); % number of dimensions
```

In other words, `ndims(x)` is the largest value of `dim`, no less than two, for which `size(x, dim)` is different from one. Here are a few examples

```
x = ones(2,1) % 2-dimensional
x = ones(2,1,1,1) % 2-dimensional
x = ones(1,0) % 2-dimensional
x = ones(1,2,3,0,0) % 5-dimensional
x = ones(2,3,0,0,1) % 4-dimensional
x = ones(3,0,0,1,2) % 5-dimensional
```

3.2.2 Singleton dimensions

A “singleton dimension” is a dimension along which the length is one. That is, if `size(x, dim)` is one, then `dim` is a singleton dimension. If, in addition, `dim` is larger than `ndims(x)`, then `dim` is called a “trailing singleton dimension”. Trailing singleton dimensions are ignored by `size` and `ndims`.

Singleton dimensions may be removed with `squeeze`. Removing singleton dimensions does not change the number of elements in an array

Flipping an array along a singleton dimension is a null-operation, that is, it has no effect, it changes nothing.

3.3 Number of elements

The number of elements in an array may be obtained with `numel`, e.g., `numel(x)` is the number of elements in `x`. The number of elements is simply the product of the length along all dimensions, that is, `prod(size(x))`. In particular, if the length along at least one dimension is zero, then the array has zero elements regardless of the length along the other dimensions.

4 Array indices and subscripts

To be written.

5 Creating vectors, matrices and arrays

5.1 Creating a constant array

5.1.1 When the class is determined by the scalar to replicate

To create an array whose size is `siz = [m n p q ...]` and where each element has the value `val`, use

```
X = repmat(val, siz);
```

Following are three other ways to achieve the same, all based on what `repmat` uses internally. Note that for these to work, the array `X` should not already exist

```
X(prod(siz)) = val; % array of right class and num. of elements
X = reshape(X, siz); % reshape to specified size
X(:) = X(end); % fill 'val' into X (redundant if 'val' is zero)
```

If the size is given as a cell vector `siz = {m n p q ...}`, there is no need to `reshape`

```
X(siz{:}) = val; % array of right class and size
X(:) = X(end); % fill 'val' into 'X' (redundant if 'val' is zero)
```

If `m, n, p, q, ...` are scalar variables, one may use

```
X(m,n,p,q) = val; % array of right class and size
X(:) = X(end); % fill 'val' into X (redundant if 'val' is zero)
```

The following way of creating a constant array is frequently used

```
X = val(ones(siz));
```

but this solution requires more memory since it creates an index array. Since an index array is used, it only works if `val` is a variable, whereas the other solutions above also work when `val` is a function returning a scalar value, e.g., if `val` is `Inf` or `NaN`:

```
X = NaN(ones(siz)); % this won't work unless NaN is a variable
X = repmat(NaN, siz); % here NaN may be a function or a variable
```

Avoid using

```
X = val * ones(siz);
```

since it does unnecessary multiplications and only works for classes for which the multiplication operator is defined.

5.1.2 When the class is stored in a string variable

To create an array of an arbitrary class `cls`, where `cls` is a character array (i.e., string) containing the class name, use any of the above which allows `val` to be a function call and let `val` be

```
feval(cls, val)
```

As a special case, to create an array of class `cls` with only zeros, here are two ways

```
X = repmat(feval(cls, 0), siz); % a nice one-liner

X(prod(siz)) = feval(cls, 0);
X = reshape(X, siz);
```

Avoid using

```
X = feval(cls, zeros(siz)); % might require a lot more memory
```

since it first creates an array of class `double` which might require many times more memory than `X` if an array of class `cls` requires less memory per element than a `double` array.

5.2 Special vectors

5.2.1 Uniformly spaced elements

To create a vector of uniformly spaced elements, use the `linspace` function or the `:` (colon) operator:

```
X = linspace(lower, upper, n);           % row vector
X = linspace(lower, upper, n).';       % column vector

X = lower : step : upper;              % row vector
X = ( lower : step : upper ).';       % column vector
```

If the difference `upper-lower` is not a multiple of `step`, the last element of `X`, `X(end)`, will be less than `upper`. So the condition `A(end) <= upper` is always satisfied.

6 Shifting

6.1 Vectors

To shift and rotate the elements of a vector, use

```
X([ end 1:end-1 ]);                     % shift right/down 1 element
X([ end-k+1:end 1:end-k ]);           % shift right/down k elements
X([ 2:end 1 ]);                       % shift left/up 1 element
X([ k+1:end 1:k ]);                   % shift left/up k elements
```

Note that these only work if `k` is non-negative. If `k` is an arbitrary integer one may use something like

```
X( mod((1:end)-k-1, end)+1 );         % shift right/down k elements
X( mod((1:end)+k-1, end)+1 );       % shift left/up k element
```

where a negative `k` will shift in the opposite direction of a positive `k`.

6.2 Matrices and arrays

To shift and rotate the elements of an array `X` along dimension `dim`, first initialize a subscript cell array with

```
idx = repmat({' : '}, ndims(X), 1); % initialize subscripts
n = size(X, dim);                  % length along dimension dim
```

then manipulate the subscript cell array as appropriate by using one of

```
idx{dim} = [ n 1:n-1 ];             % shift right/down/forwards 1 element
idx{dim} = [ n-k+1:n 1:n-k ];       % shift right/down/forwards k elements
idx{dim} = [ 2:n 1 ];               % shift left/up/backwards 1 element
idx{dim} = [ k+1:n 1:k ];           % shift left/up/backwards k elements
```

finally create the new array

```
Y = X(idx{:});
```

7 Replicating elements and arrays

7.1 Creating a constant array

See section 5.1.

7.2 Replicating elements in vectors

7.2.1 Replicate each element a constant number of times

Example Given

```
N = 3; A = [ 4 5 ]
```

create N copies of each element in A , so

```
B = [ 4 4 4 5 5 5 ]
```

Use, for instance,

```
B = A(ones(1,N), :);
B = B(:) .';
```

If A is a column-vector, use

```
B = A(:, ones(1,N)) .';
B = B(:);
```

Some people use

```
B = A( ceil( (1:N*length(A))/N ) );
```

but this requires unnecessary arithmetic. The only advantage is that it works regardless of whether A is a row or column vector.

7.2.2 Replicate each element a variable number of times

See section 16.5.2 about run-length decoding.

7.3 Using KRON for replicating elements

7.3.1 KRON with an matrix of ones

Using `kron` with one of the arguments being a matrix of ones, may be used to replicate elements. Firstly, since the replication is done by multiplying with a matrix of ones, it only works for classes for which the multiplication operator is defined. Secondly, it is never necessary to perform any multiplication to replicate elements. Hence, using `kron` is not the best way.

Assume A is a p -by- q matrix and that n is a non-negative integer.

Using KRON with a matrix of ones as first argument The expression

```
B = kron(ones(m,n), A);
```

may be computed more efficiently with

```
i = (1:p) .'; i = i(:, ones(1,m));
j = (1:q) .'; j = j(:, ones(1,n));
B = A(i, j);
```

or simply

```
B = repmat(A, [m n]);
```

Using KRON with a matrix of ones as second argument The expression

```
B = kron(A, ones(m, n));
```

may be computed more efficiently with

```
i = 1:p; i = i(ones(1, m), :);
j = 1:q; j = j(ones(1, n), :);
B = A(i, j);
```

7.3.2 KRON with an identity matrix

Assume A is a p -by- q matrix and that n is a non-negative integer.

Using KRON with an identity matrix as second argument The expression

```
B = kron(A, eye(n));
```

may be computed more efficiently with

```
B = zeros(p, q, n, n);
B(:, :, 1:n+1:n^2) = repmat(A, [1 1 n]);
B = permute(B, [3 1 4 2]);
B = reshape(B, [n*p n*q]);
```

or the following, which does not explicitly use either p or q

```
B = zeros([size(A) n n]);
B(:, :, 1:n+1:n^2) = repmat(A, [1 1 n]);
B = permute(B, [3 1 4 2]);
B = reshape(B, n*size(A));
```

Using KRON with an identity matrix as first argument The expression

```
B = kron(eye(n), A);
```

may be computed more efficiently with

```
B = zeros(p, q, n, n);
B(:, :, 1:n+1:n^2) = repmat(A, [1 1 n]);
B = permute(B, [1 3 2 4]);
B = reshape(B, [n*p n*q]);
```

or the following, which does not explicitly use either p or q

```
B = zeros([size(A) n n]);
B(:, :, 1:n+1:n^2) = repmat(A, [1 1 n]);
B = permute(B, [1 3 2 4]);
B = reshape(B, n*size(A));
```

8 Reshaping arrays

8.1 Subdividing 2D matrix

Assume X is an m -by- n matrix.

8.1.1 Create 4D array

To create a p -by- q -by- m/p -by- n/q array Y where the i, j submatrix of X is $Y(:, :, i, j)$, use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = permute( Y, [ 1 3 2 4 ] );
```

Now,

```
X = [ Y(:, :, 1, 1)  Y(:, :, 1, 2)  ...  Y(:, :, 1, n/q)
      Y(:, :, 2, 1)  Y(:, :, 2, 2)  ...  Y(:, :, 2, n/q)
      ...          ...          ...  ...
      Y(:, :, m/p, 1) Y(:, :, m/p, 2) ... Y(:, :, m/p, n/q) ];
```

To restore X from Y use

```
X = permute( Y, [ 1 3 2 4 ] );
X = reshape( X, [ m n ] );
```

8.1.2 Create 3D array (columns first)

Assume you want to create a p -by- q -by- $m*n/(p*q)$ array Y where the i, j submatrix of X is $Y(:, :, i+(j-1)*m/p)$. E.g., if A, B, C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = cat( 3, A, C, B, D );
```

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = permute( Y, [ 1 3 2 4 ] );
Y = reshape( Y, [ p q m*n/(p*q) ] );
```

Now,

```
X = [ Y(:, :, 1)  Y(:, :, m/p+1)  ...  Y(:, :, (n/q-1)*m/p+1)
      Y(:, :, 2)  Y(:, :, m/p+2)  ...  Y(:, :, (n/q-1)*m/p+2)
      ...          ...          ...  ...
      Y(:, :, m/p) Y(:, :, 2*m/p)  ...  Y(:, :, n/q*m/p) ];
```

To restore X from Y use

```
X = reshape( Y, [ p q m/p n/q ] );
X = permute( X, [ 1 3 2 4 ] );
X = reshape( X, [ m n ] );
```

8.1.3 Create 3D array (rows first)

Assume you want to create a p -by- q -by- $m*n/(p*q)$ array Y where the i, j submatrix of X is $Y(:, :, j+(i-1)*n/q)$. E.g., if A, B, C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = cat( 3, A, B, C, D );
```

use

```
Y = reshape( X, [ p m/p n ] );
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ p q m*n/(p*q) ] );
```

Now,

$$X = \begin{bmatrix} Y(:, :, 1) & Y(:, :, 2) & \dots & Y(:, :, n/q) \\ Y(:, :, n/q+1) & Y(:, :, n/q+2) & \dots & Y(:, :, 2*n/q) \\ \dots & \dots & \dots & \dots \\ Y(:, :, (m/p-1)*n/q+1) & Y(:, :, (m/p-1)*n/q+2) & \dots & Y(:, :, m/p*n/q) \end{bmatrix};$$

To restore X from Y use

```
X = reshape( Y, [ p n m/p ] );
X = permute( X, [ 1 3 2 ] );
X = reshape( X, [ m n ] );
```

8.1.4 Create 2D matrix (columns first, column output)

Assume you want to create a $m*n/q$ -by- q matrix Y where the submatrices of X are concatenated (columns first) vertically. E.g., if A, B, C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = [ A
      C
      B
      D ];
```

use

```
Y = reshape( X, [ m q n/q ] );
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ m*n/q q ] );
```

To restore X from Y use

```
X = reshape( Y, [ m n/q q ] );
X = permute( X, [ 1 3 2 ] );
X = reshape( X, [ m n ] );
```

8.1.5 Create 2D matrix (columns first, row output)

Assume you want to create a p -by- $m*n/p$ matrix Y where the submatrices of X are concatenated (columns first) horizontally. E.g., if A, B, C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = [ A C B D ];
```

use

```
Y = reshape( X, [ p m/p q n/q ] )
Y = permute( Y, [ 1 3 2 4 ] );
Y = reshape( Y, [ p m*n/p ] );
```

To restore X from Y use

```
Z = reshape( Y, [ p q m/p n/q ] );
Z = permute( Z, [ 1 3 2 4 ] );
Z = reshape( Z, [ m n ] );
```

8.1.6 Create 2D matrix (rows first, column output)

Assume you want to create a $m*n/q$ -by- q matrix Y where the submatrices of X are concatenated (rows first) vertically. E.g., if A , B , C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = [ A
      B
      C
      D ];
```

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = permute( Y, [ 1 4 2 3 ] );
Y = reshape( Y, [ m*n/q q ] );
```

To restore X from Y use

```
X = reshape( Y, [ p n/q m/p q ] );
X = permute( X, [ 1 3 4 2 ] );
X = reshape( X, [ m n ] );
```

8.1.7 Create 2D matrix (rows first, row output)

Assume you want to create a p -by- $m*n/p$ matrix Y where the submatrices of X are concatenated (rows first) horizontally. E.g., if A , B , C and D are p -by- q matrices, convert

```
X = [ A B
      C D ];
```

into

```
Y = [ A B C D ];
```

use

```
Y = reshape( X, [ p m/p n ] );
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ p m*n/p ] );
```

To restore X from Y use

```
X = reshape( Y, [ p n m/p ] );
X = permute( X, [ 1 3 2 ] );
X = reshape( X, [ m n ] );
```

8.2 Stacking and unstacking pages

Assume X is a m -by- n -by- p array and you want to create an $m*p$ -by- n matrix Y that contains the pages of X stacked vertically. E.g., if A, B, C , etc. are m -by- n matrices, then, to convert

```
X = cat(3, A, B, C, ...);
```

into

```
Y = [ A
      B
      C
      ... ];
```

use

```
Y = permute( X, [ 1 3 2 ] );
Y = reshape( Y, [ m*p n ] );
```

To restore X from Y use

```
X = reshape( Y, [ m p n ] );
X = permute( X, [ 1 3 2 ] );
```

9 Rotating matrices and arrays

9.1 Rotating 2D matrices

To rotate an m -by- n matrix X , k times 90° counterclockwise one may use

```
Y = rot90(X, k);
```

or one may do it like this

```
Y = X(:,n:-1:1).';           % rotate 90 degrees counterclockwise
Y = X(m:-1:1,:).';         % rotate 90 degrees clockwise
Y = X(m:-1:1,n:-1:1);      % rotate 180 degrees
```

In the above, one may replace m and n with `end`.

9.2 Rotating ND arrays

Assume X is an ND array and one wants the rotation to be vectorized along higher dimensions. That is, the same rotation should be performed on all 2D slices $X(:, :, i, j, \dots)$.

Rotating 90 degrees counterclockwise

```
s = size(X); % size vector
v = [ 2 1 3:ndims(X) ]; % dimension permutation vector
Y = permute( X(:,s(2):-1:1,:), v );
Y = reshape( Y, s(v) );
```

Rotating 180 degrees

```
s = size(X);
Y = reshape( X(s(1):-1:1,s(2):-1:1,:), s );
```

or the one-liner

```
Y = reshape( X(end:-1:1,end:-1:1,:), size(X) );
```

Rotating 90 clockwise

```
s = size(X); % size vector
v = [ 2 1 3:ndims(X) ]; % dimension permutation vector
Y = reshape( X(s(1):-1:1,:), s );
Y = permute( Y, v );
```

or the one-liner

```
Y = permute(reshape(X(end:-1:1,:), size(X)), [2 1 3:ndims(X)]);
```

9.3 Rotating ND arrays around an arbitrary axis

When rotating an ND array X we need to specify the axis around which the rotation should be performed. The general case is to rotate an array around an axis perpendicular to the plane spanned by dim1 and dim2 . In the cases above, the rotation was performed around an axis perpendicular to a plane spanned by dimensions one (rows) and two (columns). Note that a rotation changes nothing if both $\text{size}(X, \text{dim1})$ and $\text{size}(X, \text{dim2})$ is one.

```
% Largest dimension number we have to deal with.
nd = max( [ ndims(X) dim1 dim2 ] );

% Initialize subscript cell array.
v = repmat({':'}, [nd 1]);
```

then, depending on how to rotate, use

Rotate 90 degrees counterclockwise

```
v{dim2} = size(X, dim2) :-1:1;
Y = X(v{:});
d = 1:nd;
d([ dim1 dim2 ]) = [ dim2 dim1 ];
Y = permute(X, d);
```

Rotate 180 degrees

```
v{dim1} = size(X,dim1):-1:1;
v{dim2} = size(X,dim2):-1:1;
Y = X(v{:});
```

Rotate 90 degrees clockwise

```
v{dim1} = size(X,dim1):-1:1;
Y = X(v{:});
d = 1:nd;
d([ dim1 dim2 ]) = [ dim2 dim1 ];
Y = permute(X, d);
```

9.4 Block-rotating 2D matrices**9.4.1 “Inner” vs “outer” block rotation**

When talking about block-rotation of arrays, we have to differentiate between two different kinds of rotation. Lacking a better name I chose to call it “inner block rotation” and “outer block rotation”. Inner block rotation is a rotation of the elements within each block, preserving the position of each block within the array. Outer block rotation rotates the blocks but does not change the position of the elements within each block.

An example will illustrate: An inner block rotation 90 degrees counterclockwise will have the following effect

```
[ A B C      [ rot90(A) rot90(B) rot90(C)
  D E F  =>   rot90(D) rot90(E) rot90(F)
  G H I ]     rot90(G) rot90(H) rot90(I) ]
```

However, an outer block rotation 90 degrees counterclockwise will have the following effect

```
[ A B C      [ C F I
  D E F  =>   B E H
  G H I ]     A D G ]
```

In all the examples below, it is assumed that X is an m -by- n matrix of p -by- q blocks.

9.4.2 “Inner” block rotation 90 degrees counterclockwise

General case To perform the rotation

$$\begin{array}{ccc}
 X = [A & B & \dots & [\text{rot90}(A) & \text{rot90}(B) & \dots \\
 & C & D & \dots & \text{rot90}(C) & \text{rot90}(D) & \dots \\
 & \dots & \dots &] & \dots & \dots & \dots]
 \end{array} \Rightarrow$$

use

```

Y = reshape( X, [ p m/p q n/q ] );
Y = Y(:, :, q:-1:1, :);           % or Y = Y(:, :, end:-1:1, :);
Y = permute( Y, [ 3 2 1 4 ] );
Y = reshape( Y, [ q*m/p p*n/q ] );

```

Special case: m=p To perform the rotation

$$[A \ B \ \dots] \Rightarrow [\text{rot90}(A) \ \text{rot90}(B) \ \dots]$$

use

```

Y = reshape( X, [ p q n/q ] );
Y = Y(:, q:-1:1, :);           % or Y = Y(:, end:-1:1, :);
Y = permute( Y, [ 2 1 3 ] );
Y = reshape( Y, [ q m*n/q ] ); % or Y = Y(:, :);

```

Special case: n=q To perform the rotation

$$\begin{array}{ccc}
 X = [A & & [\text{rot90}(A) \\
 & B & \text{rot90}(B) \\
 & \dots & \dots]
 \end{array} \Rightarrow$$

use

```

Y = X(:, q:-1:1);           % or Y = X(:, end:-1:1);
Y = reshape( Y, [ p m/p q ] );
Y = permute( Y, [ 3 2 1 ] );
Y = reshape( Y, [ q*m/p p ] );

```

9.4.3 “Inner” block rotation 180 degrees

General case To perform the rotation

$$X = \begin{bmatrix} A & B & \dots & \dots \\ C & D & \dots & \dots \\ \dots & \dots & \dots & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \text{rot90}(A,2) & \text{rot90}(B,2) & \dots & \dots \\ \text{rot90}(C,2) & \text{rot90}(D,2) & \dots & \dots \\ \dots & \dots & \dots & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = Y(p:-1:1, :, q:-1:1, :);           % or Y = Y(end:-1:1, :, end:-1:1, :);
Y = reshape( Y, [ m n ] );
```

Special case: m=p To perform the rotation

$$\begin{bmatrix} A & B & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \text{rot90}(A,2) & \text{rot90}(B,2) & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p q n/q ] );
Y = Y(p:-1:1, q:-1:1, :);             % or Y = Y(end:-1:1, end:-1:1, :);
Y = reshape( Y, [ m n ] );           % or Y = Y(:, :);
```

Special case: n=q To perform the rotation

$$X = \begin{bmatrix} A & \dots \\ B & \dots \\ \dots & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \text{rot90}(A,2) & \dots \\ \text{rot90}(B,2) & \dots \\ \dots & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q ] );
Y = Y(p:-1:1, :, q:-1:1);           % or Y = Y(end:-1:1, :, end:-1:1);
Y = reshape( Y, [ m n ] );
```

9.4.4 “Inner” block rotation 90 degrees clockwise**General case** To perform the rotation
$$\begin{array}{ccc}
 X = [A & B & \dots & [\text{rot90}(A,3) & \text{rot90}(B,3) & \dots \\
 & C & D & \dots & \text{rot90}(C,3) & \text{rot90}(D,3) & \dots \\
 & \dots & \dots &] & \dots & \dots & \dots]
 \end{array} \Rightarrow$$

use

```

Y = reshape( X, [ p m/p q n/q ] );
Y = Y(p:-1:1, :, :, :); % or Y = Y(end:-1:1, :, :, :);
Y = permute( Y, [ 3 2 1 4 ] );
Y = reshape( Y, [ q*m/p p*n/q ] );

```

Special case: m=p To perform the rotation
$$[A \ B \ \dots] \Rightarrow [\text{rot90}(A,3) \ \text{rot90}(B,3) \ \dots]$$

use

```

Y = X(p:-1:1, :); % or Y = X(end:-1:1, :);
Y = reshape( Y, [ p q n/q ] );
Y = permute( Y, [ 2 1 3 ] );
Y = reshape( Y, [ q m*n/q ] ); % or Y = Y(:, :);

```

Special case: n=q To perform the rotation
$$\begin{array}{ccc}
 X = [A & & [\text{rot90}(A,3) \\
 & B & \text{rot90}(B,3) \\
 & \dots & \dots]
 \end{array} \Rightarrow$$

use

```

Y = reshape( X, [ p m/p q ] );
Y = Y(p:-1:1, :, :); % or Y = Y(end:-1:1, :, :);
Y = permute( Y, [ 3 2 1 ] );
Y = reshape( Y, [ q*m/p p ] );

```

9.4.5 “Outer” block rotation 90 degrees counterclockwise

General case To perform the rotation

$$X = \begin{bmatrix} A & B & \dots \\ C & D & \dots \\ \dots & \dots & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \dots & \dots \\ B & D & \dots \\ A & C & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = Y(:, :, :, n/q:-1:1); % or Y = Y(:, :, :, end:-1:1);
Y = permute( Y, [ 1 4 3 2 ] );
Y = reshape( Y, [ p*n/q q*m/p ] );
```

Special case: m=p To perform the rotation

$$\begin{bmatrix} A & B & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \dots \\ B \\ A \end{bmatrix}$$

use

```
Y = reshape( X, [ p q n/q ] );
Y = Y(:, :, n/q:-1:1); % or Y = Y(:, :, end:-1:1);
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ m*n/q q ] );
```

Special case: n=q To perform the rotation

$$X = \begin{bmatrix} A \\ B \\ \dots \end{bmatrix} \Rightarrow \begin{bmatrix} A & B & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q ] );
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ p n*m/p ] ); % or Y(:, :);
```

9.4.6 “Outer” block rotation 180 degrees**General case** To perform the rotation

$$\begin{array}{ccc}
 X = \begin{bmatrix} A & B & \dots \\ C & D & \dots \\ \dots & \dots & \dots \end{bmatrix} & \Rightarrow & \begin{bmatrix} \dots & \dots \\ \dots & D & C \\ \dots & B & A \end{bmatrix}
 \end{array}$$

use

```

Y = reshape( X, [ p m/p q n/q ] );
Y = Y(:,m/p:-1:1, :, n/q:-1:1);      % or Y = Y(:,end:-1:1, :, end:-1:1);
Y = reshape( Y, [ m n ] );

```

Special case: m=p To perform the rotation

$$\begin{bmatrix} A & B & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \dots & B & A \end{bmatrix}$$

use

```

Y = reshape( X, [ p q n/q ] );
Y = Y(:, :, n/q:-1:1);                % or Y = Y(:, :, end:-1:1);
Y = reshape( Y, [ m n ] );            % or Y = Y(:, :);

```

Special case: n=q To perform the rotation

$$\begin{array}{ccc}
 X = \begin{bmatrix} A \\ B \\ \dots \end{bmatrix} & \Rightarrow & \begin{bmatrix} \dots \\ B \\ A \end{bmatrix}
 \end{array}$$

use

```

Y = reshape( X, [ p m/p q ] );
Y = Y(:, m/p:-1:1, :);                % or Y = Y(:, end:-1:1, :);
Y = reshape( Y, [ m n ] );

```

9.4.7 “Outer” block rotation 90 degrees clockwise

General case To perform the rotation

$$X = \begin{bmatrix} A & B & \dots & \\ & C & D & \dots \\ & & & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \dots & C & A & \\ & & & D & B \\ & & & & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = Y(:,m/p:-1:1, :, :); % or Y = Y(:,end:-1:1, :, :);
Y = permute( Y, [ 1 4 3 2 ] );
Y = reshape( Y, [ p*n/q q*m/p ] );
```

Special case: m=p To perform the rotation

$$\begin{bmatrix} A & B & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} A \\ B \\ \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p q n/q ] );
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ m*n/q q ] );
```

Special case: n=q To perform the rotation

$$X = \begin{bmatrix} A \\ B \\ \dots \end{bmatrix} \Rightarrow \begin{bmatrix} \dots & B & A \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q ] );
Y = Y(:,m/p:-1:1, :); % or Y = Y(:,end:-1:1, :);
Y = permute( Y, [ 1 3 2 ] );
Y = reshape( Y, [ p n*m/p ] );
```

9.5 Blocktransposing a 2D matrix

9.5.1 “Inner” blocktransposing

Assume X is an m -by- n matrix and you want to subdivide it into p -by- q submatrices and transpose as if each block was an element. E.g., if A, B, C and D are p -by- q matrices, convert

$$X = \begin{bmatrix} A & B & \dots & \\ & C & D & \dots \\ & & & \dots \end{bmatrix} \Rightarrow \begin{bmatrix} A.' & B.' & \dots & \\ & C.' & D.' & \dots \\ & & & \dots \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = permute( Y, [ 3 2 1 4 ] );
Y = reshape( Y, [ q*m/p p*n/q ] );
```

9.5.2 “Outer” blocktransposing

Assume X is an m -by- n matrix and you want to subdivide it into p -by- q submatrices and transpose as if each block was an element. E.g., if A, B, C and D are p -by- q matrices, convert

$$X = \begin{bmatrix} A & B & \dots & \\ C & D & \dots & \\ \dots & \dots & & \end{bmatrix} \Rightarrow \begin{bmatrix} A & C & \dots & \\ B & D & \dots & \\ \dots & \dots & & \end{bmatrix}$$

use

```
Y = reshape( X, [ p m/p q n/q ] );
Y = permute( Y, [ 1 4 3 2 ] );
Y = reshape( Y, [ p*n/q q*m/p ] );
```

10 Multiply arrays

10.1 Multiply each 2D slice with the same matrix (element-by-element)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is an m -by- n matrix and you want to construct a new m -by- n -by- p -by- q -by-... array Z , where

```
Z(:, :, i, j, ...) = X(:, :, i, j, ...) .* Y;
```

for all $i=1, \dots, p, j=1, \dots, q$, etc. This can be done with nested for-loops, or by the following vectorized code

```
sx = size(X);
Z = X .* repmat(Y, [1 1 sx(3:end)]);
```

10.2 Multiply each 2D slice with the same matrix (left)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is a k -by- m matrix and you want to construct a new k -by- n -by- p -by- q -by-... array Z , where

```
Z(:, :, i, j, ...) = Y * X(:, :, i, j, ...);
```

for all $i=1, \dots, p, j=1, \dots, q$, etc. This can be done with nested for-loops, or by the following vectorized code

```
sx = size(X);
sy = size(Y);
Z = reshape(Y * X(:, :), [sy(1) sx(2:end)]);
```

The above works by reshaping X so that all 2D slices $X(:, :, i, j, \dots)$ are placed next to each other (horizontal concatenation), then multiply with Y , and then reshaping back again.

The $X(:, :)$ is simply a short-hand for `reshape(X, [sx(1) prod(sx)/sx(1)])`.

10.3 Multiply each 2D slice with the same matrix (right)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is an n -by- k matrix and you want to construct a new m -by- n -by- p -by- q -by-... array Z , where

```
Z(:, :, i, j, ...) = X(:, :, i, j, ...) * Y;
```

for all $i=1, \dots, p$, $j=1, \dots, q$, etc. This can be done with nested for-loops, or by vectorized code. First create the variables

```

sx = size(X);
sy = size(Y);
dx = ndims(X);

```

Then use the fact that

$$Z(:, :, i, j, \dots) = X(:, :, i, j, \dots) * Y = (Y' * X(:, :, i, j, \dots)')';$$

so the multiplication $Y' * X(:, :, i, j, \dots)'$ can be solved by the method in section 10.2.

```

Xt = conj(permute(X, [2 1 3:dx]));
Z = Y' * Xt(:, :);
Z = reshape(Z, [sy(2) sx(1) sx(3:dx)]);
Z = conj(permute(Z, [2 1 3:dx]));

```

Note how the complex conjugate transpose ($'$) on the 2D slices of X was replaced by a combination of `permute` and `conj`.

Actually, because signs will cancel each other, we can simplify the above by removing the calls to `conj` and replacing the complex conjugate transpose ($'$) with the non-conjugate transpose ($.'$). The code above then becomes

```

Xt = permute(X, [2 1 3:dx]);
Z = Y.' * Xt(:, :);
Z = reshape(Z, [sy(2) sx(1) sx(3:dx)]);
Z = permute(Z, [2 1 3:dx]);

```

An alternative method is to perform the multiplication $X(:, :, i, j, \dots) * Y$ directly but that requires that we stack all 2D slices $X(:, :, i, j, \dots)$ on top of each other (vertical concatenation), multiply, and unstack. The code is then

```

Xt = permute(X, [1 3:dx 2]);
Xt = reshape(Xt, [prod(sx)/sx(2) sx(2)]);
Z = Xt * Y;
Z = reshape(Z, [sx(1) sx(3:dx) sy(2)]);
Z = permute(Z, [1 dx 2:dx-1]);

```

The first two lines perform the stacking and the two last perform the unstacking.

10.4 Multiply matrix with every element of a vector

Assume X is an m -by- n matrix and v is a vector with length p . How does one write

```

Y = zeros(m, n, p);
for i = 1:p
Y(:, :, i) = X * v(i);
end

```

with no for-loop? One way is to use

```

Y = reshape(X(:)*v, [m n p]);

```

For the more general problem where X is an m -by- n -by- p -by- q -by- \dots array and v is a p -by- q -by- \dots array, the for-loop

```

Y = zeros(m, n, p, q, ...);
...
for j = 1:q
    for i = 1:p
        Y(:,:,i,j,...) = X(:,:,i,j,...) * v(i,j,...);
    end
end
...

```

may be written as

```

sx = size(X);
Z = X .* repmat(reshape(v, [1 1 sx(3:end)]), [sx(1) sx(2)]);

```

10.5 Multiply each 2D slice with corresponding element of a vector

Assume X is an m -by- n -by- p array and v is a row vector with length p . How does one write

```

Y = zeros(m, n, p);
for i = 1:p
    Y(:,:,i) = X(:,:,i) * v(i);
end

```

with no for-loop? One way is to use

```

Y = X .* repmat(reshape(v, [1 1 p]), [m n]);

```

10.6 Outer product of all rows in a matrix

Assume X is an m -by- n matrix. How does one create an n -by- n -by- m matrix Y so that, for all i from 1 to m ,

```

Y(:,:,i) = X(i,:) * X(i,:);

```

The obvious for-loop solution is

```

Y = zeros(n, n, m);
for i = 1:m
    Y(:,:,i) = X(i,:) * X(i,:);
end

```

a non-for-loop solution is

```

j = 1:n;
Y = reshape(repmat(X', n, 1) .* X(:,j(ones(n, 1),:)).', [n n m]);

```

Note the use of the non-conjugate transpose in the second factor to ensure that it works correctly also for complex matrices.

10.7 Keeping only diagonal elements of multiplication

Assume X and Y are two m -by- n matrices and that W is an n -by- n matrix. How does one vectorize the following for-loop

```

Z = zeros(m, 1);
for i = 1:m
    Z(i) = X(i, :)*W*Y(i, :)' ;
end

```

Two solutions are

```

Z = diag(X*W*Y') ; % (1)
Z = sum(X*W.*conj(Y), 2) ; % (2)

```

Solution (1) does a lot of unnecessary work, since we only keep the n diagonal elements of the n^2 computed elements. Solution (2) only computes the elements of interest and is significantly faster if n is large.

10.8 Products involving the Kronecker product

The following is based on a posting by Paul Fackler <paul_fackler@ncsu.edu> to the Usenet news group comp.soft-sys.matlab.

Kronecker products of the form `kron(A, eye(n))` are often used to premultiply (or post-multiply) another matrix. If this is the case it is not necessary to actually compute and store the Kronecker product. Assume A is an p -by- q matrix and that B is a q -by- n -by- m matrix.

Then the following two p -by- n -by- m matrices are identical

```

C1 = kron(A, eye(n))*B;
C2 = reshape(reshape(B.', [n*m q])*A.', [p*n m]).';

```

The following two p -by- n -by- m matrices are also identical.

```

C1 = kron(eye(n), A)*B;
C2 = reshape(A*reshape(B, [q n*m]), [p*n m]);

```

11 Divide arrays

11.1 Divide each 2D slice with the same matrix (element-by-element)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is an m -by- n matrix and you want to construct a new m -by- n -by- p -by- q -by-... array Z , where

```

Z(:, :, i, j, ...) = X(:, :, i, j, ...) ./ Y;

```

for all $i=1, \dots, p$, $j=1, \dots, q$, etc. This can be done with nested for-loops, or by the following vectorized code

```

sx = size(X);
Z = X./ repmat(Y, [1 1 sx(3:end)]);

```

11.2 Divide each 2D slice with the same matrix (left)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is an m -by- m matrix and you want to construct a new m -by- n -by- p -by- q -by-... array Z , where

```

Z(:, :, i, j, ...) = Y \ X(:, :, i, j, ...);

```

for all $i=1, \dots, p$, $j=1, \dots, q$, etc. This can be done with nested for-loops, or by the following vectorized code

```

Z = reshape(Y\X(:, :), size(X));

```

11.3 Divide each 2D slice with the same matrix (right)

Assume X is an m -by- n -by- p -by- q -by-... array and Y is an m -by- m matrix and you want to construct a new m -by- n -by- p -by- q -by-... array Z , where

$$Z(:, :, i, j, \dots) = X(:, :, i, j, \dots) / Y;$$

for all $i=1, \dots, p$, $j=1, \dots, q$, etc. This can be done with nested for-loops, or by the following vectorized code

```

sx = size(X);
dx = ndims(X);
Xt = reshape(permute(X, [1 3:dx 2]), [prod(sx)/sx(2) sx(2)]);
Z = Xt/Y;
Z = permute(reshape(Z, sx([1 3:dx 2])), [1 dx 2:dx-1]);

```

The third line above builds a 2D matrix which is a vertical concatenation (stacking) of all 2D slices $X(:, :, i, j, \dots)$. The fourth line does the actual division. The fifth line does the opposite of the third line.

The five lines above might be simplified a little by introducing a dimension permutation vector

```

sx = size(X);
dx = ndims(X);
v = [1 3:dx 2];
Xt = reshape(permute(X, v), [prod(sx)/sx(2) sx(2)]);
Z = Xt/Y;
Z = ipermute(reshape(Z, sx(v)), v);

```

If you don't care about readability, this code may also be written as

```

sx = size(X);
dx = ndims(X);
v = [1 3:dx 2];
Z = ipermute(reshape(reshape(permute(X, v), ...
[prod(sx)/sx(2) sx(2)]/Y, sx(v)), v);

```

12 Calculating distances

12.1 Euclidean distance

The Euclidean distance from \mathbf{x}_i to \mathbf{y}_j is

$$\mathbf{d}_{ij} = \|\mathbf{x}_i - \mathbf{y}_j\| = \sqrt{(x_{1i} - y_{1j})^2 + \dots + (x_{pi} - y_{pj})^2}$$

12.2 Distance between two points

To calculate the Euclidean distance from a point represented by the vector \mathbf{x} to another point represented by the vector \mathbf{y} , use one of

```

d = norm(x-y);
d = sqrt(sum(abs(x-y).^2));

```

12.3 Euclidean distance vector

Assume X is an m -by- p matrix representing m points in p -dimensional space and y is a 1 -by- p vector representing a single point in the same space. Then, to compute the m -by- 1 distance vector d where $d(i)$ is the Euclidean distance between $X(i, :)$ and y , use

```
d = sqrt(sum(abs(X - repmat(y, [m 1])).^2, 2));
d = sqrt(sum(abs(X - y(ones(m,1),:)).^2, 2)); % inline call to repmat
```

12.4 Euclidean distance matrix

Assume X is an m -by- p matrix representing m points in p -dimensional space and Y is an n -by- p matrix representing another set of points in the same space. Then, to compute the m -by- n distance matrix D where $D(i, j)$ is the Euclidean distance $X(i, :)$ between $Y(j, :)$, use

```
D = sqrt(sum(abs( repmat(permute(X, [1 3 2]), [1 n 1]) ...
- repmat(permute(Y, [3 1 2]), [m 1 1]) ).^2, 3));
```

The following code inlines the call to `repmat`, but requires to temporary variables unless one doesn't mind changing X and Y

```
Xt = permute(X, [1 3 2]);
Yt = permute(Y, [3 1 2]);
D = sqrt(sum(abs( Xt(:,ones(1,n),:) ...
- Yt(ones(1,m),:,:) ).^2, 3));
```

The distance matrix may also be calculated without the use of a 3-D array:

```
i = (1:m).'; % index vector for x
i = i(:,ones(1,n)); % index matrix for x
j = 1:n; % index vector for y
j = j(ones(1,m),:); % index matrix for y
D = zeros(m, n); % initialise output matrix
D(:) = sqrt(sum(abs(X(i(:),:) - Y(j(:),:)).^2, 2));
```

12.5 Special case when both matrices are identical

If X and Y are identical one may use the following, which is nothing but a rewrite of the code above

```
D = sqrt(sum(abs( repmat(permute(X, [1 3 2]), [1 m 1]) ...
- repmat(permute(X, [3 1 2]), [m 1 1]) ).^2, 3));
```

One might want to take advantage of the fact that D will be symmetric. The following code first creates the indices for the upper triangular part of D . Then it computes the upper triangular part of D and finally lets the lower triangular part of D be a mirror image of the upper triangular part.

```
[ i j ] = find(triu(ones(m), 1)); % trick to get indices
D = zeros(m, m); % initialise output matrix
D( i + m*(j-1) ) = sqrt(sum(abs( X(i,:) - X(j,:) ).^2, 2));
D( j + m*(i-1) ) = D( i + m*(j-1) );
```

12.6 Mahalanobis distance

The Mahalanobis distance from a vector \mathbf{y}_j to the set $\mathcal{X} = \{\mathbf{x}_1, \dots, \mathbf{x}_{n_x}\}$ is the distance from \mathbf{y}_j to $\bar{\mathbf{x}}$, the centroid of \mathcal{X} , weighted according to C_x , the variance matrix of the set \mathcal{X} . I.e.,

$$\mathbf{d}_j^2 = (\mathbf{y}_j - \bar{\mathbf{x}})' \mathbf{C}_x^{-1} (\mathbf{y}_j - \bar{\mathbf{x}})$$

where

$$\bar{\mathbf{x}} = \frac{1}{n_x} \sum_{i=1}^{n_x} \mathbf{x}_i \quad \text{and} \quad \mathbf{C}_x = \frac{1}{n_x - 1} \sum_{i=1}^{n_x} (\mathbf{x}_i - \bar{\mathbf{x}})(\mathbf{x}_i - \bar{\mathbf{x}})'$$

Assume \mathbf{Y} is an n_y -by- p matrix containing a set of vectors and \mathbf{X} is an n_x -by- p matrix containing another set of vectors, then the Mahalanobis distance from each vector $\mathbf{Y}(j, :)$ (for $j=1, \dots, n_y$) to the set of vectors in \mathbf{X} can be calculated with

```

nx = size(X, 1);           % size of set in X
ny = size(Y, 1);           % size of set in Y
m = mean(X);
C = cov(X);
d = zeros(ny, 1);
for j = 1:ny
    d(j) = (Y(j,:) - m) / C * (Y(j,:) - m)';
end

```

which is computed more efficiently with the following code which does some inlining of functions (`mean` and `cov`) and vectorization

```

nx = size(X, 1);           % size of set in X
ny = size(Y, 1);           % size of set in Y

m = sum(X, 1)/nx;          % centroid (mean)
Xc = X - m(ones(nx,1),:); % distance to centroid of X
C = (Xc' * Xc)/(nx - 1);  % variance matrix
Yc = Y - m(ones(ny,1),:); % distance to centroid of Y
d = sum(Yc/C.*Yc, 2);     % Mahalanobis distances

```

In the complex case, the last line has to be written as

```

d = real(sum(Yc/C.*conj(Yc), 2)); % Mahalanobis distances

```

The call to `conj` is to make sure it also works for the complex case. The call to `real` is to remove “numerical noise”.

The Statistics Toolbox contains the function `mahal` for calculating the Mahalanobis distances, but `mahal` computes the distances by doing an orthogonal-triangular (QR) decomposition of the matrix C . The code above returns the same as `d = mahal(Y, X)`.

Special case when both matrices are identical If \mathbf{Y} and \mathbf{X} are identical in the code above, the code may be simplified somewhat. The for-loop becomes

```

n = size(X, 1);           % size of set in X
m = mean(X);
C = cov(X);
d = zeros(n, 1);
for j = 1:n
    d(j) = (Y(j,:) - m) / C * (Y(j,:) - m)';
end

```

which is computed more efficiently with

```
n = size(x, 1);
m = sum(x, 1)/n;           % centroid (mean)
Xc = x - m(ones(n,1),:);  % distance to centroid of X
C = (Xc' * Xc)/(n - 1);   % variance matrix
d = sum(Xc/C.*Xc, 2);     % Mahalanobis distances
```

Again, to make it work in the complex case, the last line must be written as

```
d = real(sum(Xc/C.*conj(Xc), 2)); % Mahalanobis distances
```

13 Statistics, probability and combinatorics

13.1 Discrete uniform sampling with replacement

To generate an array X with size vector s , where X contains a random sample from the numbers $1, \dots, n$ use

```
X = ceil(n*rand(s));
```

To generate a sample from the numbers a, \dots, b use

```
X = a + floor((b-a+1)*rand(s));
```

13.2 Discrete weighted sampling with replacement

Assume p is a vector of probabilities that sum up to 1. Then, to generate an array X with size vector s , where the probability of $X(i)$ being i is $p(i)$ use

```
m = length(p);           % number of probabilities
c = cumsum(p);           % cumulative sum
R = rand(s);
X = ones(s);
for i = 1:m-1
    X = X + (R > c(i));
end
```

Note that the number of times through the loop depends on the number of probabilities and not the sample size, so it should be quite fast even for large samples.

13.3 Discrete uniform sampling without replacement

To generate a sample of size k from the integers $1, \dots, n$, one may use

```
X = randperm(n);
x = X(1:k);
```

although that method is only practical if N is reasonably small.

13.4 Combinations

“Combinations” is what you get when you pick k elements, without replacement, from a sample of size n , and consider the order of the elements to be irrelevant.

13.4.1 Counting combinations

The number of ways to pick k elements, without replacement, from a sample of size n is $\binom{n}{k}$ which is calculate with

```
c = nchoosek(n, k);
```

one may also use the definition directly

```
k = min(k, n-k);      % use symmetry property
c = round(prod( (n-k+1):n) ./ (1:k) );
```

which is safer than using

```
k = min(k, n-k);      % use symmetry property
c = round( prod((n-k+1):n) / prod(1:k) );
```

which may overflow. Unfortunately, both n and k have to be scalars. If n and/or k are vectors, one may use the fact that

$$\binom{n}{k} = \frac{n!}{k!(n-k)!} = \frac{\Gamma(n+1)}{\Gamma(k+1)\Gamma(n-k+1)}$$

and calculate this in with

```
round(exp(gammain(n+1) - gammain(k+1) - gammain(n-k+1)))
```

where the `round` is just to remove any “numerical noise” that might have been introduced by `gammain` and `exp`.

13.4.2 Generating combinations

To generate a matrix with all possible combinations of n elements taken k at a time, one may use the MATLAB function `nchoosek`. That function is rather slow compared to the `choosenk` function which is a part of Mike Brookes’ Voicebox (Speech recognition toolbox) whose homepage is <http://www.ee.ic.ac.uk/hp/staff/dmb/voicebox/voicebox.html>

For the special case of generating all combinations of n elements taken 2 at a time, there is a neat trick

```
[ x(:,2) x(:,1) ] = find(tril(ones(n), -1));
```

13.5 Permutations

13.5.1 Counting permutations

```
p = prod(n-k+1:n);
```

13.5.2 Generating permutations

To generate a matrix with all possible permutations of n elements, one may use the function `perms`. That function is rather slow compared to the `permutes` function which is a part of Mike Brookes’ Voicebox (Speech recognition toolbox) whose homepage is at <http://www.ee.ic.ac.uk/hp/staff/dmb/voicebox/voicebox.html>

14 Types of arrays

14.1 Numeric array

A numeric array is an array that contains real or complex numerical values including `NaN` and `Inf`. An array is numeric if its class is `double`, `single`, `uint8`, `uint16`, `uint32`, `int8`, `int16` or `int32`. To see if an array `x` is numeric, use

```
isnumeric(x)
```

To disallow `NaN` and `Inf`, we can *not* just use

```
isnumeric(x) & ~any(isnan(x(:))) & ~any(isinf(x(:)))
```

since, by default, `isnan` and `isinf` are only defined for class `double`. A solution that works is to use the following, where `tf` is either true or false

```
tf = isnumeric(x);
if isa(x, 'double')
    tf = tf & ~any(isnan(x(:))) & ~any(isinf(x(:)))
end
```

If one is only interested in arrays of class `double`, the above may be written as

```
isa(x, 'double') & ~any(isnan(x(:))) & ~any(isinf(x(:)))
```

Note that there is no need to call `isnumeric` in the above, since a `double` array is always numeric.

14.2 Real array

MATLAB has a subtle distinction between arrays that have a zero imaginary part and arrays that do not have an imaginary part:

```
isreal(0) % no imaginary part, so true
isreal(complex(0, 0)) % imaginary part (which is zero), so false
```

The essence is that `isreal` returns false (i.e., 0) if space has been allocated for an imaginary part. It doesn't care if the imaginary part is zero, if it is present, then `isreal` returns false.

To see if an array `x` is real in the sense that it has no non-zero imaginary part, use

```
~any(imag(x(:)))
```

Note that `x` might be real without being numeric; for instance, `isreal('a')` returns true, but `isnumeric('a')` returns false.

14.3 Identify real or purely imaginary elements

To see which elements are real or purely imaginary, use

```
imag(x) == 0 % identify real elements
~imag(x) % ditto (might be faster)

real(x) ~= 0 % identify purely imaginary elements
logical(real(x)) % ditto (might be faster)
```

14.4 Array of negative, non-negative or positive values

To see if the elements of the real part of all elements of `x` are negative, non-negative or positive values, use

```
x < 0                % identify negative elements
all(x(:) < 0)       % see if all elements are negative

x >= 0              % identify non-negative elements
all(x(:) >= 0)     % see if all elements are non-negative

x > 0               % identify positive elements
all(x(:) > 0)     % see if all elements are positive
```

14.5 Array of integers

To see if an array `x` contains real or complex integers, use

```
x == round(x)          % identify (possibly complex) integers
~imag(x) & x == round(x) % identify real integers

% see if x contains only (possibly complex) integers
all(x(:) == round(x(:)))

% see if x contains only real integers
isreal(x) & all(x(:) == round(x(:)))
```

14.6 Scalar

To see if an array `x` is scalar, i.e., an array with exactly one element, use

```
all(size(x) == 1)      % is a scalar
prod(size(x) == 1)    % is a scalar
any(size(x) ~= 1)     % is not a scalar
prod(size(x) ~= 1)    % is not a scalar
```

An array `x` is scalar or empty if the following is true

```
isempty(x) | all(size(x) == 1) % is scalar or empty
prod(size(x)) <= 1             % is scalar or empty
prod(size(x)) > 1              % is not scalar or empty
```

14.7 Vector

An array `x` is a non-empty vector if the following is true

```
~isempty(x) & sum(size(x) > 1) <= 1 % is a non-empty vector
isempty(x) | sum(size(x) > 1) > 1  % is not a non-empty vector
```

An array `x` is a possibly empty vector if the following is true

```
sum(size(x) > 1) <= 1 % is a possibly empty vector
sum(size(x) > 1) > 1  % is not a possibly empty vector
```

An array `x` is a possibly empty row or column vector if the following is true (the two methods are equivalent)

```
ndims(x) <= 2 & sum(size(x) > 1) <= 1
ndims(x) <= 2 & ( size(x,1) <= 1 | size(x,2) <= 1 )
```

Add `~isempty(x) & ...` for `x` to be non-empty.

14.8 Matrix

An array `x` is a possibly empty matrix if the following is true

```
ndims(x) == 2           % is a possibly empty matrix
ndims(x) > 2           % is not a possibly empty matrix
```

Add `~isempty(x) & ...` for `x` to be non-empty.

14.9 Array slice

An array `x` is a possibly empty 2-D slice if the following is true

```
sum(size(x) > 1) <= 2   % is a possibly empty 2-D slice
sum(size(x) > 1) > 2   % is not a possibly empty 2-D slice
```

15 Logical operators and comparisons

15.1 List of logical operators

MATLAB has the following logical operators

<code>and</code> &	Logical AND
<code>or</code>	Logical OR
<code>not</code> ~	Logical NOT
<code>xor</code>	Logical EXCLUSIVE OR
<code>any</code>	True if any element of vector is nonzero
<code>all</code>	True if all elements of vector are nonzero

15.2 Rules for logical operators

Here is a list of some of the rules that apply to the logical operators in MATLAB.

```
~(a & b) = ~a | ~b
~(a | b) = ~a & ~b

xor(a,b) = (a | b) & ~(a & b)
~xor(a,b) = ~(a | b) | (a & b)

~all(x) = any(~x)
~any(x) = all(~x)
```

15.3 Quick tests before slow ones

If several tests are combined with binary logical operators (&, | and xor), make sure to put the fast ones first. For instance, to see if the array `x` is a real positive finite scalar double integer, one could use

```
isa(x,'double') & isreal(x) & ~any(isinf(x(:)))
& all(x(:) > 0) & all(x(:) == round(x(:))) & all(size(x) == 1)
```

but if `x` is a large array, the above might be very slow since it has to look at each element at least once (the `isinf` test). The following is faster and requires less typing

```
isa(x,'double') & isreal(x) & all(size(x) == 1) ...
& ~isinf(x) & x > 0 & x == round(x)
```

Note how the last three tests get simplified because, since we have put the test for “scalarness” before them, we can safely assume that `x` is scalar. The last three tests aren’t even performed at all unless `x` is a scalar.

16 Miscellaneous

This section contains things that don’t fit anywhere else.

16.1 Accessing elements on the diagonal

The common way of accessing elements on the diagonal of a matrix is to use the `diag` function. However, sometimes it is useful to know the linear index values of the diagonal elements. To get the linear index values of the elements on the following diagonals

```
(1)      (2)      (3)      (4)      (5)
[ 1 0 0   [ 1 0 0   [ 1 0 0 0   [ 0 0 0   [ 0 1 0 0
  0 2 0     0 2 0     0 2 0 0     1 0 0     0 0 2 0
  0 0 3 ]   0 0 3     0 0 3 0 ]   0 2 0     0 0 0 3 ]
           0 0 0 ]           0 0 3 ]
```

one may use

```
1 : m+1 : m*m           % square m-by-m matrix (1)
1 : m+1 : m*n           % m-by-n matrix where m >= n (2)
1 : m+1 : m*m           % m-by-n matrix where m <= n (3)
1 : m+1 : m*min(m,n)    % any m-by-n matrix

m-n+1 : m+1 : m*n       % m-by-n matrix where m >= n (4)
(n-m)*m+1 : m+1 : m*n   % m-by-n matrix where m <= n (5)
```

To get the linear index values of the elements on the following anti-diagonals

```
(1)      (2)      (3)      (4)      (5)
[ 0 0 3   [ 0 0 0   [ 0 0 3 0   [ 0 0 3   [ 0 0 0 3
  0 2 0     0 0 3     0 2 0 0     0 2 0     0 0 2 0
  1 0 0 ]   0 2 0     1 0 0 0 ]   1 0 0     0 1 0 0 ]
           1 0 0 ]           0 0 0 ]
```

one may use

```

m : m-1 : (m-1)*m+1      % square m-by-m matrix (1)
m : m-1 : (m-1)*n+1      % m-by-n matrix where m >= n (2)
m : m-1 : (m-1)*m+1      % m-by-n matrix where m <= n (3)
m : m-1 : (m-1)*min(m,n)+1 % any m-by-n matrix

m-n+1 : m-1 : m*(n-1)+1  % m-by-n matrix where m >= n (4)
(n-m+1)*m : m-1 : m*(n-1)+1 % m-by-n matrix where m <= n (5)

```

16.2 Creating index vector from index limits

Given two vectors `lo` and `hi`. How does one create an index vector

```
idx = [lo(1):hi(1) lo(2):hi(2) ...]
```

A straightforward for-loop solution is

```

m = length(lo);          % length of input vectors
idx = [];                % initialize index vector
for i = 1:m
    idx = [ idx lo(i):hi(i) ];
end

```

which unfortunately requires a lot of memory copying since a new `x` has to be allocated each time through the loop. A better for-loop solution is one that allocates the required space and then fills in the elements afterwards. This for-loop solution above may be several times faster than the first one

```

m = length(lo);          % length of input vectors
len = hi - lo + 1;       % length of each "run"
n = sum(len);            % length of index vector
lst = cumsum(len);       % last index in each run

idx = zeros(1, n);      % initialize index vector
for i = 1:m
    idx(lst(i)-len(i)+1:lst(i)) = lo(i):hi(i);
end

```

Neither of the for-loop solutions above can compete with the the solution below which has no for-loops. It uses `cumsum` rather than the `:` to do the incrementing in each run and may be many times faster than the for-loop solutions above.

```

m = length(lo);          % length of input vectors
len = hi - lo + 1;       % length of each "run"
n = sum(len);            % length of index vector

idx = ones(1, n);       % initialize index vector
idx(1) = lo(1);
len(1) = len(1)+1;
idx(cumsum(len(1:end-1))) = lo(2:m) - hi(1:m-1);
idx = cumsum(idx);

```

If fails, however, if `lo(i) > hi(i)` for any `i`. Such a case will create an empty vector anyway, so the problem can be solved by a simple pre-processing step which removing the elements for which `lo(i) > hi(i)`

```

i = lo <= hi;
lo = lo(i);
hi = hi(i);

```

There also exists a one-line solution which is very compact, but not as fast as the no-for-loop solution above

```
x = eval(['[' sprintf('%d:%d,', [lo ; hi]) '']]);
```

16.3 Matrix with different incremental runs

Given a vector of positive integers

```
a = [ 3 2 4 ];
```

How does one create the matrix where the *i*th column contains the vector `1:a(i)` possibly padded with zeros:

```
b = [ 1 1 1
      2 2 2
      3 0 3
      0 0 4 ];
```

One way is to use a for-loop

```
n = length(a);
b = zeros(max(a), n);
for k = 1:n
    t = 1:a(k);
    b(t,k) = t(:);
end
```

and here is a way to do it without a for-loop

```
[bb aa] = ndgrid(1:max(a), a);
b = bb .* (bb <= aa)
```

or the more explicit

```
m = max(a);
aa = a(:)';
aa = aa(ones(m, 1), :);
bb = (1:m)';
bb = bb(:,ones(length(a), 1));
b = bb .* (bb <= aa);
```

To do the same, only horizontally, use

```
[aa bb] = ndgrid(a, 1:max(a));
b = bb .* (bb <= aa)
```

or

```
m = max(a);
aa = a(:);
aa = aa(:,ones(m, 1));
bb = 1:m;
bb = bb(ones(length(a), 1), :);
b = bb .* (bb <= aa);
```

16.4 Finding indices

16.4.1 First non-zero element in each column

How does one find the index and values of the first non-zero element in each column. For instance, given

```
x = [ 0 1 0 0
      4 3 7 0
      0 0 2 6
      0 9 0 5 ];
```

how does one obtain the vectors

```
i = [ 2 1 2 3 ];      % row numbers
v = [ 4 1 7 6 ];      % values
```

If it is known that all columns have at least one non-zero value

```
[i, j, v] = find(x);
t = logical(diff([0;j]));
i = i(t);
v = v(t);
```

If some columns might not have a non-zero value

```
[it, jt, vt] = find(x);
t = logical(diff([0;jt]));
i = repmat(NaN, [size(x,2) 1]);
v = i;
i(jt(t)) = it(t);
v(jt(t)) = vt(t);
```

16.4.2 First non-zero element in each row

How does one find the index and values of the first non-zero element in each row. For instance, given

```
x = [ 0 1 0 0
      4 3 7 0
      0 0 2 6
      0 9 0 5 ];
```

how does one obtain the vectors

```
j = [ 1 2 3 1 ];      % column numbers
v = [ 1 4 2 9 ];      % values
```

If it is known that all rows have at least one non-zero value

```
[i, j, v] = find(x);
[i, k] = sort(i);
t = logical(diff([0;i]));
j = j(k(t));
v = v(k(t));
```

If some rows might not have a non-zero value

```

[it, jt, vt] = find(x);
[it, k] = sort(it);
t = logical(diff([0;it]));
j = repmat(NaN, [size(x,1) 1]);
v = j;
j(it(t)) = jt(k(t));
v(it(t)) = vt(k(t));

```

16.4.3 Last non-zero element in each row

How does one find the index of the last non-zero element in each row. That is, given

```

x = [ 0 9 7 0 0 0
      5 0 0 6 0 3
      0 0 0 0 0 0
      8 0 4 2 1 0 ];

```

how does one obtain the vector

```

j = [ 3
      6
      0
      5 ];

```

One way is of course to use a for-loop

```

m = size(x, 1);
j = zeros(m, 1);
for i = 1:m
    k = find(x(i,:) ~= 0);
    if length(k)
        j(i) = k(end);
    end
end

```

or

```

m = size(x, 1);
j = zeros(m, 1);
for i = 1:m
    k = [ 0 find(x(i,:) ~= 0) ];
    j(i) = k(end);
end

```

but one may also use

```

j = sum(cumsum((x(:,end:-1:1) ~= 0), 2) ~= 0, 2);

```

To find the index of the last non-zero element in each column, use

```

i = sum(cumsum((x(end:-1:1,:) ~= 0), 1) ~= 0, 1);

```

16.5 Run-length encoding and decoding

16.5.1 Run-length encoding

Assuming `x` is a vector

```
x = [ 4 4 5 5 5 6 7 7 8 8 8 8 ]
```

and one wants to obtain the two vectors

```
len = [ 2 3 1 2 4 ];           % run lengths
val = [ 4 5 6 7 8 ];          % values
```

one can get the run length vector `len` by using

```
len = diff([ 0 find(x(1:end-1) ~= x(2:end)) length(x) ]);
```

and the value vector `val` by using one of

```
val = x([ find(x(1:end-1) ~= x(2:end)) length(x) ]);
val = x(logical([ x(1:end-1) ~= x(2:end) 1 ]));
```

which of the two above that is faster depends on the data. For more or less sorted data, the first one seems to be faster in most cases. For random data, the second one seems to be faster. These two steps required to get both the run-lengths and values may be combined into

```
i = [ find(x(1:end-1) ~= x(2:end)) length(x) ];
len = diff([ 0 i ]);
val = x(i);
```

16.5.2 Run-length decoding

Given the run-length vector `len` and the value vector `val`, one may create the full vector `x` by using

```
i = cumsum(len);           % length(len) flops
j = zeros(1, i(end));
j(i(1:end-1)+1) = 1;       % length(len) flops
j(1) = 1;
x = val(cumsum(j));        % sum(len) flops
```

the above method requires approximately $2 \cdot \text{length}(\text{len}) + \text{sum}(\text{len})$ flops. There is a way that only requires approximately $\text{length}(\text{len}) + \text{sum}(\text{len})$ flops, but is slightly slower (not sure why, though).

```
len(1) = len(1)+1;
i = cumsum(len);           % length(len) flops
j = zeros(1, i(end)-1);
j(i(1:end-1)) = 1;
j(1) = 1;
x = val(cumsum(j));        % sum(len) flops
```

This following method requires approximately $\text{length}(\text{len}) + \text{sum}(\text{len})$ flops and only four lines of code, but is slower than the two methods suggested above.

```
i = cumsum([ 1 len ]);     % length(len) flops
j = zeros(1, i(end)-1);
j(i(1:end-1)) = 1;
x = val(cumsum(j));        % sum(len) flops
```

16.6 Counting bits

Assume `x` is an array of non-negative integers. The number of set bits in each element, `nsetbits`, is

```
nsetbits = reshape(sum(dec2bin(x)-'0', 2), size(x));
```

or

```
bin = dec2bin(x);
nsetbits = reshape(sum(bin,2) - '0'*size(bin,2), size(x));
```

The following solution is slower, but requires less memory than the above so it is able to handle larger arrays

```
nsetbits = zeros(size(x));
k = find(x);
while length(k)
    nsetbits = nsetbits + bitand(x, 1);
    x = bitshift(x, -1);
    k = k(logical(x(k)));
end
```

The total number of set bits, `nsetbits`, may be computed with

```
bin = dec2bin(x);
nsetbits = sum(bin(:)) - '0'*prod(size(bin));

nsetbits = 0;
k = find(x);
while length(k)
    nsetbits = nsetbits + sum(bitand(x, 1));
    x = bitshift(x, -1);
    k = k(logical(x(k)));
end
```

Glossary

null-operation an operation which has no effect on the operand

operand an argument on which an operator is applied

singleton dimension a dimension along which the length is zero

subscript context an expression used as an array subscript is in a subscript context

vectorization taking advantage of the fact that many operators and functions can perform the same operation on several elements in an array without requiring the use of a for-loop
